

NHS Satisfaction Analysis

British Social Attitudes Survey 2021 | R | Quantitative Research

Research question

Does NHS satisfaction differ across selected socio-demographic characteristics in the British Social Attitudes Survey 2021?

Data and method

The project uses the British Social Attitudes Survey 2021. NHS satisfaction is treated as a continuous outcome. The analysis uses descriptive statistics, an independent-samples t-test, a chi-square test and simple linear regression with $\alpha = 0.05$.

Results

Complete-case sample: $N = 3,307$. Mean NHS satisfaction = 2.60. Sex difference: $t = -0.78$, $p = 0.437$, not statistically significant.

Education association: chi-square = 10.84, $df = 6$, $p = 0.093$, not statistically significant at the 5% level.

Age regression slope = 0.00117, $p = 0.717$, with approximately zero R-squared. There is no evidence of a linear age relationship.

Additional descriptive comparisons

Mean satisfaction was 2.63 for married/cohabiting respondents, 2.52 for divorced/separated respondents, 2.88 for widowed respondents and 2.55 for single respondents. Respondents with children averaged 2.56 versus 2.63 for those without children.

Conclusion and limitations

The examined socio-demographic variables provide limited evidence of systematic differences in NHS satisfaction. The data are observational and cross-sectional, so findings should not be interpreted causally.
